Abstract

Maintaining genome integrity in the mammalian germline is essential and enormously complex. Hundreds of proteins comprise pathways involved in DNA replication, and hundreds more are mobilized to repair DNA damage [1]. While loss-of-function mutations in any of the genes encoding these proteins might lead to elevated mutation rates, *mutator alleles* have largely eluded detection in mammals.

DNA replication and repair proteins often recognize particular sequence motifs or excise lesions at specific nucleotides. Thus, we might expect that the spectrum of de novo mutations — i.e, the frequency of each individual mutation type (C>T, A>G, etc.) — will differ between genomes that harbor either a mutator or wild-type allele at a given locus. Previously, we used quantitative trait locus (QTL) mapping to discover a mutator allele near the DNA repair gene *Mutyh* that increases the rate of *de novo* C>A germline mutation in a collection of recombinant inbred lines (RILs) known as the BXDs [2,3].

In this study, we developed a new method to detect alleles that affect the mutation spectrum in biparental RILs. By applying this method to mutation data from the BXDs, we confirmed the activity of the germline mutator locus near *Mutyh*, and discovered an additional C>A germline mutator locus on chromosome 6 that overlaps *Ogg1*, a key partner of *Mutyh* in base-excision repair of oxidative DNA damage [4]. Strikingly, BXDs with the mutator allele near *Ogg1* do not exhibit elevated rates of C>A germline mutation unless they also possess the mutator allele near *Mutyh*, but BXDs with both alleles exhibit even higher C>A mutation rates than those with either one alone.

To our knowledge, these new methods for analyzing mutation spectra reveal the first evidence of epistasis between mammalian germline mutator alleles, and may be applicable to mutation data from humans and other model organisms.

Introduction

The germline mutation rate is a fundamental parameter in population genetics, and reflects the complex interplay between DNA replication and repair pathways, exogenous sources of DNA damage, and life-history traits. *Mutator alleles* may explain some of the within- and between-species variation in germline mutation rates [5], but have proven challenging to identify in mammalian genomes.

Germline mutator alleles are difficult to detect for a number of reasons, including the fidelity of germline genome replication and the effects of selection on mutators. On average, humans are born with 30 to 50 single-nucleotide de novo germline mutations per haploid genome [6,7]; in mice, that number is closer to 10 or 15 [8]. Due to the low baseline germline mutation rate in many mammals, it can be challenging to ascertain sequencing data from enough haplotypes to reliably detect those with significantly elevated de novo mutation counts. Moreover, in a population of sufficiently large N_e (effective population size), large-effect mutator alleles will likely be efficiently purged by negative selection. The estimated selection coefficient on a mutator allele is approximately $2s\Delta U$ [9], where s is the mean selective coefficient on a new deleterious mutation and ΔU is the excess number of new deleterious mutations caused by the mutator allele; the product of s and s is multiplied by 2 to account for the average number of generations for which mutator is linked to the excess mutations it causes.

Compared to haplotypes that harbor wild-type alleles at a particular locus, those harboring mutator alleles will likely carry an excess of total germline mutations. Indeed, candidate germline mutator loci have been discovered in human genomes by identifying haplotypes with significantly more derived

alleles than the population mean [10]. However, protein-coding genes involved in DNA replication and repair often recognize particular sequence motifs or excise lesions at specific nucleotides [5]. Thus, we might also expect the spectrum of de novo mutations — that is, the frequency of each individual mutation type (C>T, A>G, etc.) — to differ between genomes that carry either a mutator or wild-type allele at a given locus.

In 2022, we discovered a germline mutator allele in mice by analyzing whole-genome sequencing data from 152 recombinant inbred lines (RILs). Commonly known as the BXDs [3], these RILs were derived from either F2 or advanced intercrosses of C57BL/6J and DBA/2J, two laboratory strains that exhibit significant differences in their germline mutation spectra [11]. Since the BXD RILs were maintained via brother-sister mating for up to 180 generations and housed in a controlled laboratory environment, they were an ideal population for mutator allele discovery. Namely, each line accumulated hundreds or thousands of germline mutations on a nearly-homozygous linear mosaic of parental B and D haplotypes, while the effects of negative selection on new and standing variation were attenuated by strict inbreeding [12]. We used quantitative trait locus (QTL) mapping to identify a locus on chromosome 4 that was strongly associated with the C>A germline mutation rate in the BXDs [2]. The QTL overlapped *Mutyh*, which encodes a protein that normally prevents C>A mutations by repairing oxidative DNA damage [4], and we hypothesized that missense mutations in *Mutyh* were responsible for a 50% increase in the C>A mutation rate between BXDs with either parental haplotype at the QTL [2].

In this study, we developed a new method to detect alleles that affect the mutation spectrum in biparental RILs, and applied it to *de novo* germline mutation data from the BXDs. We assessed its power to detect candidate mutator alleles, re-identified the mutator near *Mutyh*, and discovered compelling evidence of epistasis between two germline mutator alleles that augment the C>A germline mutation rate.

Materials and Methods

Identifying de novo germline mutations in the BXD RILs

The BXD resource currently comprises a total of 152 recombinant inbred lines (RILs). RILs were derived from either F2 or advanced intercrosses, and subsequently inbred by brother-sister mating for up to 180 generations [3]. BXDs were generated in distinct breeding "epochs," which were each initiated with a distinct cross of C57BL/6J and DBA/2J parents; epochs 1, 2, 4, and 6 were derived from F2 crosses, while epochs 3 and 5 were derived from advanced intercrosses [3]. Previously, we analyzed whole-genome sequencing data from the BXDs and identified candidate *de novo* germline mutations in each line [2]. A detailed description of the methods used for DNA extraction, sequencing, alignment, and variant processing, as well as the characteristics of the *de novo* mutations, are available in a previous manuscript [2].

Briefly, we identified private single-nucleotide mutations in each BXD that were absent from all other RILs, as well as from the C57BL/6J and DBA/2J parents. We required each private variant to be meet the following criteria:

- genotyped as either homozygous or heterozygous for the alternate allele, with at least 90% of sequencing reads supporting the alternate allele
- supported by at least 10 sequencing reads
- Phred-scaled genotype quality of at least 20

- must not overlap regions of the genome annotated as segmental duplications or simple repeats in GRCm38/mm10
- must occur on a parental haplotype that was inherited by at least one other BXD at the same locus; these other BXDs must be homozygous for the reference allele at the variant site

A new approach to discover germline mutator alleles

Using the existing catalog of *de novo* germline mutations in the BXDs, we developed a new approach to discover loci that affect the germline *de novo* mutation spectrum in biparental RILs (Figure 1).

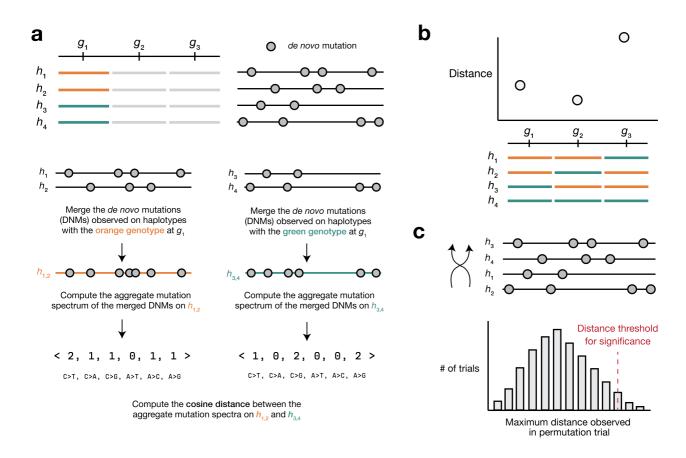

Figure 1: Overview of inter-haplotype distance method for discovering mutator alleles. a) A population of four haplotypes has been genotyped at three informative markers; each haplotype also harbors private de novo germline mutations. At each informative marker, we compute an aggregate de novo germline mutation spectrum in the haplotypes that carry either parental allele, and calculate the cosine distance between the two aggregate spectra. b) We repeat the process outlined in a) for every informative marker along the genome. c) To assess the significance of any cosine distance peaks in b), we perform a permutation test by shuffling the labels associated with each haplotype's mutation data and running a genome-wide distance scan. In each of N permutations, we record the maximum distance encountered at any locus in the distance scan. Finally, we calculate the 1-p percentile of that maximum distance distribution to obtain a genome-wide cosine distance threshold at the specified value of p.

We assume that a collection of haplotypes has been genotyped at informative markers, and that *de novo* germline mutations have been identified on each haplotype.

At each informative marker, we divide haplotypes into two groups based on the parental allele that they inherited. We then compute a k-mer mutation spectrum using the aggregate mutation counts in each haplotype group. The k-mer mutation spectrum contains the frequency of every possible k-mer mutation type in a collection of mutations, and can be represented as a vector of size $6\times 4^{k-1}$ after collapsing by strand complement. For example, the 1-mer mutation spectrum is 6-element vector that contains the frequencies of C>T, C>G, C>A, A>G, A>T, and A>C mutations.

At each marker, we then calculate the cosine distance between the aggregate mutation spectra of haplotypes with either parental allele. The cosine distance between two vectors ${\bf A}$ and ${\bf B}$ is defined as

$$D_C = 1 - rac{\mathbf{A} \cdot \mathbf{B}}{||\mathbf{A}|| \; ||\mathbf{B}||}$$

where $||\mathbf{A}||$ and $||\mathbf{B}||$ are the L^2 (or Euclidean) norms of \mathbf{A} and \mathbf{B} , respectively. The cosine distance metric has a number of favorable properties for comparing mutation spectra. Since cosine distance does not take the magnitude of vectors into account, it can be used to compare two spectra with unequal total mutation counts (even if those total counts are relatively small). Additionally, by calculating the cosine distance between mutation spectra, we avoid the need to perform separate comparisons of mutation counts at each individual k-mer mutation type.

Inspired by methods from QTL mapping [13], we use permutation tests to establish genome-wide cosine distance thresholds. In each of N permutation trials, we randomly shuffle the per-haplotype mutation data such that haplotype labels no longer correspond to the correct mutation counts. Using the shuffled mutation data, we perform a genome-wide distance scan as described above, and record the maximum distance observed at any locus. After N permutations (usually 10,000), we compute the 1-p percentile of the maximum distance distribution, and use that percentile value as a genome-wide significance threshold (for example, at p=0.05).

The inter-haplotype distance method was implemented in Python, and relies heavily on the following Python libraries: numpy, pandas, matplotlib, scikit-learn, pandera, seaborn, and numba [14,15,16,17,18,19,20].

Additional documentation is available on GitHub [21], along with a reproducible Snakemake [22] workflow for running the method from start to finish using the BXDs (including downloading the mutation data, downloading genotypes, and running a genome-wide distance scan).

Simulations to assess the power of the inter-haplotype distance approach

We performed a series of simple simulations to estimate our power to detect alleles that affect the germline mutation spectrum in biparental RILs using the inter-haplotype distance method.

First, we simulate the k-mer mutation spectrum in a population of h haplotypes. We assume that exactly $\frac{h}{2}$ of the haplotypes are under the effects of a mutator allele that increases the mutation rate of a particular mutation type(s) by an effect size e. We simulate m mutations on each haplotype as follows:

We first define a vector of 1-mer mutation probabilities:

$$P = (0.4, 0.1, 0.075, 0.075, 0.075, 0.275)$$

These probabilities sum to 1 and correspond to the expected frequencies of C>T, C>A, C>G, A>T, A>C, and A>G *de novo* germline mutations in mice, respectively [8].

If we are simulating the 3-mer mutation spectrum, we modify the vector of mutation probabilities P to be length 96, and assign every 3-mer mutation type a value of $\frac{P_c}{16}$, where P_c is the probability of the

"central" mutation type associated with the 3-mer mutation type. In other words, each of the 16 possible NCN>NTN 3-mer mutation types would be assigned a mutation probability of $\frac{P_c}{16}=\frac{0.4}{16}=0.025$.

To simulate the mutation spectrum on the *wild-type* haplotypes, we define a matrix C of size $(\frac{h}{2},n)$, where $n=6\times 4^{k-1}$ (i.e., the number of k-mer mutation types being simulated). First, we generate a vector of lambda values by scaling the mutation probabilities by the number of mutations we wish to simulate:

$$\lambda = Pm$$

Then, we populate the matrix C by taking a single Poisson draw from the vector of λ values for each mutation type on each haplotype. Thus, for every row i in the matrix (i.e., for every haplotype), we perform the following for mutation type j:

$$C_{i,j} = \operatorname{Pois}(\lambda_j)$$

To simulate the mutation spectrum on the $\frac{h}{2}$ mutator haplotypes, we define a new matrix C' of size $(\frac{h}{2},n)$ as defined above. We then multiply the lambda value of a particular mutation type (or multiple mutation types) by the mutator effect size e to obtain λ' . Then, for every row i in the matrix:

$$C'_{i,j} = \operatorname{Pois}(\lambda'_j)$$

When k=1, we only augment the effect size of one mutation type at a time, but when k=3, we augment a fraction (25%, 50%, or 100%) of the 3-mer mutation types associated with a single "central" mutation type.

After generating mutator and wild-type haplotypes, we compute the aggregate mutation spectrum in either group by summing the columns of C and C'. We then calculate the cosine distance between the two aggregate spectra, which we call the "focal" distance D_f . To determine whether D_f is greater than what we'd expect by chance, we perform a permutation test.

First, we concatenate the matrices of wild-type and mutator haplotype spectra:

$$A = \left[egin{array}{c} C \ C' \end{array}
ight]$$

Then, in each of N=1,000 trials, we randomly permute the rows of A. In every permutation, we consider the row indices from $\left[0,\frac{h}{2}\right)$ to correspond to the wild-type haplotypes, and the row indices from $\left[\frac{h}{2},h\right)$ to correspond to the mutator haplotypes. We then compute the cosine distance between the aggregate spectra of the wild-type and mutator haplotypes. If fewer than 5% of the N permutations produces a cosine distance greater than or equal to D_f , we say that the approach successfully identified the mutator allele. For every combination of simulation parameters (h,m,e,a) and so on) we perform 100 trials and record the number of trials in which we successfully identify the mutator allele.

Applying the inter-haplotype distance method to the BXDs

We downloaded previously-generated BXD *de novo* germline mutation data from the GitHub repository associated with our previous manuscript, which was also archived at Zenodo [2,23,24], and downloaded a CSV file of BXD genotypes at 7,320 informative markers from GeneNetwork [25,26]. We also downloaded relevant metadata about each BXD RIL from the manuscript describing the updated BXD resource [3].

As in our previous manuscript [2], we included mutation data from a subset of the 152 BXDs in our inter-haplotype distance scans. We removed any BXDs that had been inbred for fewer than 20 generations, as it takes approximately 20 generations of strict brother-sister mating for an RIL genome to become >98% homozygous [27]. As a result, any potential mutator allele would almost certainly be either fixed or lost after 20 generations. If fixed, the allele would remain linked to any excess mutations it causes for the duration of subsequent inbreeding, and its effects would be detectable using our methods. Additionally, a strain only meets the canonical definition of "inbred" if it has been subject to brother-sister mating for at least 20 generations [28]. is one We also removed the BXD68 RIL from our genome-wide scans, since we previously discovered a hyper-mutator phenotype in that strain; the C>A germline mutation rate in BXD68 is over 5 times the population mean, likely due to a private deleterious nonsynonymous mutation in *Mutyh* [2]. In total, we included 94 BXD RILs in our genome-wide scans.

We used Snakemake [29] to write a reproducible workflow for running the inter-haplotype distance method on the BXD dataset, which has been deposited in the GitHub repository associated with this manuscript [21].

Identifying candidate mutator alleles overlapping the chromosome 6 peak

We investigated the region implicated by our inter-haplotype distance approach on chromosome 6 by subsetting the joint-genotyped BXD VCF file (European Nucleotide Archive accession **PRJEB45429** [30]) using bcftools [31]. We defined the candidate interval surrounding the cosine distance peak on chromosome 6 as +/- 5 Mbp from the genotype marker with the largest cosine distance value (rs31001331). To predict the functional impacts of both single-nucleotide variants and indels on splicing, protein structure, etc., we annotated variants in the BXD VCF using the following snpEff [32] command:

```
java -Xmx16g -jar /path/to/snpeff/jarfile GRCm38.75 /path/to/bxd/vcf >
/path/to/uncompressed/output/vcf
```

and used cyvcf2 [33] to iterate over the annotated VCF file in order to identify nonsynonymous fixed differences between the parental C57BL/6J and DBA/2J strains.

Comparing mutation spectra between Mouse Genomes Project strains

We downloaded mutation data from a previously published analysis [11] (Supplementary File 1, Excel Table S3) that identified strain-private mutations in 29 strains that were originally whole-genome sequenced as part of the Sanger Mouse Genomes (MGP) project [34]. When comparing counts of each mutation type between MGP strains that harbored either *D* or *B* alleles at the chromosome 4 or chromosome 6 mutator loci, we adjusted mutation counts by the number of callable A, T, C, or G nucleotides in each strain as described previously [2].

Querying GeneNetwork for evidence of eQTLs at the mutator locus

We used the online GeneNetwork resource [26], which contains array- and RNA-seq-derived expression measurements in a wide variety of tissues from numerous datasets, to find *cis*-eQTLs for the DNA repair genes we implicated under the cosine distance peak on chromosome 6. On the GeneNetwork homepage (genenetwork.org), we selected the "BXD Family" **Group** and used the **Type** dropdown menu to select each of the specific expression datasets described in Table 1. In the **Get Any** text box, we then entered the gene name (*Ogg1*) and clicked **Search**. After selecting the appropriate trait ID on the next page, we used the **Mapping Tools** dropdown to run Haley-Knott regression [35] with the following parameters: WGS-based marker genotypes, 1,000 permutations for LOD threshold calculations, and controlling for BXD genotypes at the rs32497085 marker.

The exact names of the expression datasets we used for each tissue are shown in Table 1 below:

Table 1: Names of gene expression datasets used for each tissue type on GeneNetwork

Calculating the frequencies of candidate mutator alleles in wild mice

To determine the frequency of the *Ogg1* p.Thr95Ala mutation in other populations of mice, we queried a VCF file containing genome-wide variation in 67 wild-derived mice from four species of *Mus* [36]. We calculated the allele frequency of each nonsynonymous mutation in each of the four species or subspecies (*Mus musculus domesticus, Mus musculus musculus, Mus musculus castaneus*, and *Mus spretus*), including genotypes that met the following criteria:

- supported by at least 10 sequencing reads
- Phred-scaled genotype quality of at least 20

Testing for epistasis between the two mutator loci

To more formally test for the presence of epistasis between mutator alleles at the loci near *Mutyh* and *Ogg1*, we fit a linear model in the R statistical language as follows:

where Count is the count of C>A *de novo* mutations observed in each BXD RIL. ADJ_AGE is the product of the number of "callable" cytosine nucleotides in each RIL (i.e., the total number of cytosines covered by at least 10 sequencing reads in the RIL) and the number of generations for which the RIL was inbred. We included the logarithm of ADJ_AGE as an "offset" in the regression model in order to treat the response variable as a rate rather than an absolute count. The BXDs differ in both their durations of inbreeding and the proportions of their genomes that were sequenced to sufficient depth, which will influence the number of mutations we observe in each RIL. The Haplotype_A and Haplotype_B terms represent the genotypes of BXDs at markers rs52263933 and rs31001331 (the markers with peak cosine distance near *Mutyh* and *Ogg1* in the two inter-haplotype distance scans). Since each RIL is completely inbred, we considered genotypes at either locus to be binary ("B" or "D"). Using analysis of variance (ANOVA), we then compared the model incorporating an interaction effect to a model including only additive effects:

```
anova(m1, m2, test="Chisq")
```

We tested for epistasis in the Sanger Mouse Genomes Project (MGP) strains using a nearly-identical approach. In this analysis, we fit two models as follows:

where Count is the count of strain-private C>A mutations observed in each MGP strain [11]. The CALLABLE term represents the total number of cytosine and guanine nucleotides that were accessible for mutation calling in each strain, and the Haplotype_A and Haplotype_B terms represent MGP genotypes at rs52263933 and rs31001331. We compared the two models using ANOVA as described above.

Results

Benchmarking the inter-haplotype distance method using simulations

We first tested the inter-haplotype cosine distance approach using simulated data (Materials and Methods). We find that the method's power is mostly limited by the initial mutation rate of the k-mer mutation type affected by the mutator allele and the total number of de novo germline mutations in the dataset (that is, the product of the number of haplotypes and the mean number of mutations per haplotype) (Figure 2). For example, given 50 haplotypes with an average of 500 de novo germline mutations each, our method has nearly 90% power detect a mutator allele that increases the C>T de

novo mutation rate by 10%. However, the method only has about 10% power to detect a mutator of identical effect size that affects the C>G mutation rate, since C>G mutations are expected to make up a much smaller fraction of all de novo germline mutations to begin with. These simulations also demonstrate that our method is well-powered to detect large-effect mutator alleles (e.g., those that increase the mutation rate of a specific k-mer by 50%), even with a relatively small number of mutations per haplotype.

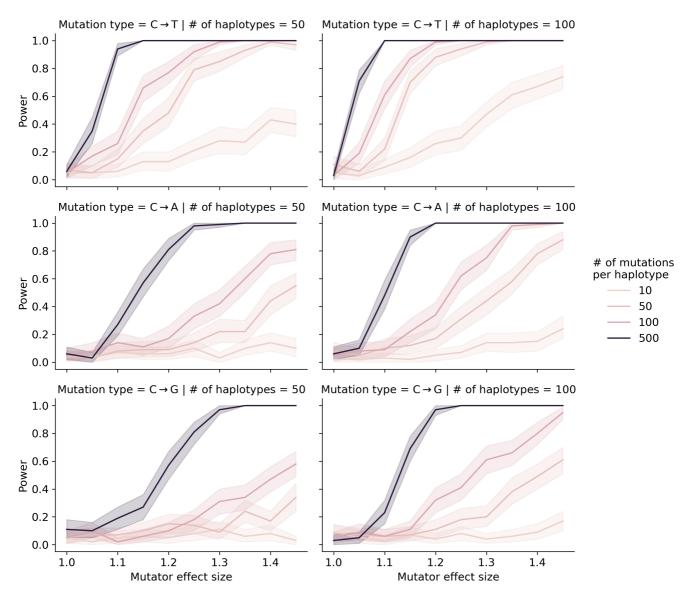

Figure 2: Simulations to assess the power of the inter-haplotype distance method. We simulated de novo germline mutations on the specified number of haplotypes, such that 50% of haplotypes were affected by a mutator allele that increased the mutation rate of the specified k-mer by the specified effect size (an effect size of 1.5 indicates a 50% increase in the mutation rate). The colors of the lines indicate the number of simulated mutations on each haplotype (before augmenting the mutation rate with a mutator allele). Given a specific combination of parameters, the y-axis denotes the fraction of 100 simulations in which the simulated mutator allele could be detected at a p-value of 0.05. Shaded areas indicate the standard deviation of that fraction.

Re-identifying the mutator allele on chromosome 4 in the BXDs

We applied our inter-haplotype distance method to 93 BXD RILs (Materials and Methods) with a total of 62,993 *de novo* germline mutations [2]. Reassuringly, we observed a large peak in cosine distance at a locus on chromosome 4 (Figure 3A; maximum distance of 9.20e-3 at marker ID rs52263933; position 116.75 Mbp in GRCm38/mm10 coordinates).

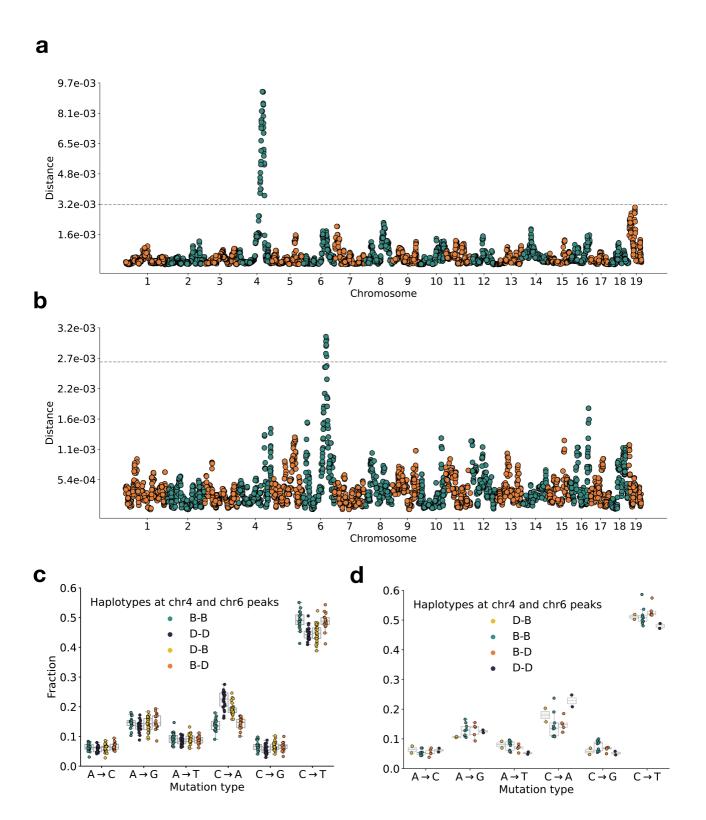

Figure 3: Results of inter-haplotype distance scans in the BXD RILs. a) Cosine distances between aggregate de novo mutation spectra on BXD haplotypes (n = 93 haplotypes; 62,993 total mutations) with either D or B alleles at 7,320 informative markers. Distance threshold at p=0.05 was calculated by performing 10,000 permutations of the BXD haplotype mutation data, and is shown as a dotted grey line. One outlier RIL with an extremely high C>A mutation rate (BXD68) was removed prior to running the distance scan. **b)** Cosine distances between aggregate de novo mutation spectra on BXD haplotypes with D alleles at rs52263933 (n = 55 haplotypes; 40,913 total mutations) and either D or B alleles at 7,320 informative markers. Distance threshold at p=0.05 was calculated by performing 10,000 permutations of the BXD haplotype mutation data, and is shown as a dotted grey line. **c)** Fractions of de novo germline mutations in BXDs with either D or B haplotypes at markers rs52263933 and rs31001331, stratified by mutation type. **d)** Fractions of de novo germline mutations in Sanger Mouse Genome Project (MGP) strains with either D or B haplotypes at markers rs52263933 and rs31001331, stratified by mutation type.

In a previous analysis, we used quantitative trait locus (QTL) mapping to identify a nearly identical locus on chromosome 4 that was significantly associated with the C>A germline mutation rate in the BXDs [2]. This locus overlaps 21 protein-coding genes that are annotated by the Gene Ontology as being involved in "DNA repair," but only one of these genes contains non-synonymous differences between the two parental strains: *Mutyh. Mutyh* encodes a protein involved in the base-excision repair of 8-oxoguanine (8-oxoG), a DNA lesion caused by oxidative damage, and prevents the accumulation of C>A mutations [4,37,38]. C>A germline mutation rates are nearly 50% higher in BXDs that inherited *D* haplotypes at marker ID rs52263933 than in those that inherited *B* haplotypes [2].

An additional germline mutator allele on chromosome 6

After confirming that the inter-haplotype distance method could recover the mutator locus overlapping Mutyh, we asked if our approach could identify additional mutator loci in the BXD. To account for the effects of the large-effect C>A germline mutator locus near Mutyh, we divided the BXD RILs into those with either D (n = 55) or B (n = 38) genotypes at rs52263933 (the marker at which we observed the highest inter-haplotype cosine distance on chromosome 4), and ran a genome-wide distance scan using each group separately (Figure 3B.

Using only the BXDs with *B* genotypes at the *Mutyh* mutator locus, we did not observe any genomewide significant peaks. But using the BXDs with *D* genotypes at the same locus, we identified a cosine distance peak on chromosome 6 (Figure 3B; maximum distance of 3.03e-3 at marker rs31001331; position 114.05 Mbp in GRCm38/mm10 coordinates). We queried the region underneath this peak (+/-5 Mbp) and discovered 87 protein-coding genes. Remarkably, only one was both annotated with the Gene Ontology term "DNA repair" and contained nonsynonymous differences between C57BL/6J and DBA/2J: *Ogg1*. *Ogg1* encodes a key member of the base-excision repair response to oxidative DNA damage, a pathway that also includes *Mutyh*. *Ogg1* harbors a single fixed nonsynonymous differences between the C57BL/6J and DBA/2J parental strains: p.Thr95Ala, at position 113,328,510 on chromosome 6 in GRCm38/mm10 coordinates.

We also considered the possibility that expression quantitative trait loci (eQTLs), rather than nonsynonymous mutations, could contribute to the C>A mutator phenotype associated to the locus on chromosome 6. Using GeneNetwork [26], we mapped cis-eQTLs for *Ogg1* in a number of tissues, including hematopoetic stem cells, kidney, and spleen. BXD genotypes near the cosine distance peak on chromosome 6 were significantly associated with *Ogg1* expression in some (but not all) tissues, and *D* genotypes were nearly always associated with decreased gene expression (Table 2). We also queried a previously published collection of eQTLs derived from Diversity Outbred (DO) mouse embryonic stem cell (mESC) expression data [39], but did not find any significant eQTLs for *Ogg1*.

Table 2: Presence or absence of cis-eQTLs for *Ogg1* in various tissues identified using GeneNetwork.

Evidence of epistasis between germline mutator alleles

Next, we more precisely characterized the effects of the *Mutyh* and *Ogg1* mutator alleles on mutation spectra in the BXDs. We observed that C>A germline mutation fractions in BXDs with *D* alleles at both mutator loci were significantly higher than C>A fractions in BXDs with *D* alleles at either locus alone (Figure 3C). However, compared to BXDs with *B* alleles at the chromosome 6 mutator locus, those with *D* alleles did not exhibit significantly higher C>A mutation fractions, indicating that the effects of the chromosome 6 mutator locus depend on the presence of a *D* allele at the chromosome 4 locus (Figure 3C). To more formally test for epistasis, we fit a linear model predicting C>A mutation rates as a function of genotypes at rs52263933 and rs31001331 (the peak markers at the chr4 and chr6 mutator loci, respectively) (Materials and Methods). A model that included an interaction term between genotypes at the two markers fit the data significantly better (p = 0.0048) than a model including only additive effects of the two markers.

To explore the effects of the two mutator loci in other inbred laboratory mice, we also compared the germline mutation spectra of Sanger Mouse Genomes Project (MGP) strains. Dumont [11] previously identified private germline mutations in 29 inbred laboratory strains; these private variants likely represent recent *de novo* germline mutations (Figure 3D). Only two of the MGP strains possess *D* genotypes at both the chromosome 4 and chromosome 6 mutator loci: DBA/1J and DBA/2J. As before, we tested for epistasis in the MGP strains by fitting two linear models predicting C>A mutation rates as a function of genotypes at rs52263933 and rs31001331. A model incorporating an interaction term between genotypes at these loci did not fit the data significantly better than a model with additive effects alone (p = 0.474). Thus, we are unable to confirm the signal of epistasis observed in the BXDs, but this may be due to the smaller number of MGP strains with *de novo* germline mutation data.

The candidate Ogg1 mutator allele is present in wild mice

To determine whether the candidate mutator allele on chromosome 6 was segregating in natural populations, we queried previously published sequencing data generated from 67 wild-derived mice [36]. These data include three subspecies of *Mus musculus*, as well as the outgroup *Mus spretus*. We found that the *D* allele in *Ogg1* was segregating at approximately 25% frequency in *Mus musculus domesticus*, the species from which C57BL/6J and DBA/2J derive the majority of their genomes [40], and was fixed in *Mus musculus musculus*, *Mus musculus castaneus*, and the outgroup *Mus spretus*.

Discussion

Epistasis between germline mutator alleles

To our knowledge, these results reveal evidence of epistasis between mammalian germline mutator alleles for the first time. BXDs with *D* alleles at the mutator locus on chromosome 6 only exhibit elevated C>A mutation rates if they also carry *D* alleles at the previously-identified [2] mutator locus on chromosome 4. And BXDs with *D* alleles at both loci have significantly higher C>A germline mutation rates than lines with *D* alleles at only one mutator locus alone (Figure 3C). This raises the exciting possibility that epistasis between mutator alleles has contributed to the evolution of germline mutation rates and spectra in mammalian genomes.

Importantly, we note that we observed epistasis between germline mutator alleles in an unnatural population; the BXDs were inbred by brother-sister mating in a highly controlled laboratory environment that attenuated the effects of natural selection on all but the most deleterious alleles [12]. However, we found the *D* allele in *Ogg1* to be at nearly 25% frequency in *Mus musculus domesticus*, the strain from which C57BL/6J and DBA/2J derive most of their genomes [40]. Since the *D* mutator haplotype on chromosome 6 does not appear to increase the C>A germline mutation rate on its own (even in a homozygous state), we hypothesize that similar alleles may be at intermediate or high frequency in other natural populations.

Causal variants underlying the mutator allele

Only one DNA repair gene overlapping the C>A mutator locus on chromosome 6 also contained nonsynonymous fixed differences between the C57BL/6J and DBA/2J founder strains: Ogg1, a proteincoding gene that participates in base-excision repair of the oxidative DNA lesion 8-oxoguanine (8oxoG) [4]. Both missense mutations and loss-of-heterozygosity in Ogg1 have been associated with initiation and progression of various types of human cancer [41,42,43]. Unrepaired 8-oxoG lesions can also lead to C>A mutations, and copy-number losses of either Ogg1 or Mutyh are linked to elevated rates of spontaneous C>A mutation in human neuroblastoma [44]. Given these various lines of evidence, we believe that Ogg1 is the most likely candidate gene to explain the additional C>A mutator phenotype in the BXDs, but it remains unclear whether the p.Thr95Ala missense mutation is the causal allele. We hypothesized that *Mutyh* missense mutations on *D* haplotypes were responsible for the large-effect C>A mutator phenotype we previously observed in the BXDs [2]. However, using highquality long-read assemblies of inbred laboratory strains, another group recently identified a ~5 kbp mobile element insertion (MEI) within the first intron of Mutyh [45] that is present on D haplotypes and absent from B haplotypes. The MEI is associated with significantly reduced expression of Mutyh in embryonic stem cells from laboratory strains, and may therefore underlie the previous C>A germline mutator phenotype in the BXDs. In light of this new evidence, we cannot discount the possibility that eQTLs associated with decreased expression of Ogg1 (Table 2) are responsible for the C>A mutator phenotype we observed in this study.

Mechanism of epistasis between Mutyh and Ogg1 mutator alleles

Mutyh and Ogg1 are key members of the base-excision repair (BER) response to 7,8-dihydro-8oxo-deoxyguanine (8-oxoG), one of the most common products of DNA damage by reactive oxygen species [4,46]. Mutyh and Ogg1 fulfill two distinct roles in the BER response to 8-oxoG. If a cell is not actively undergoing DNA replication, Ogg1 can excise the 8-oxoG lesion, leaving behind an unpaired cytosine on the opposite strand [46]. Then, additional BER proteins can incorporate an unmodified guanine and restore the appropriate G:C base-pair. However, if the 8-oxoG lesion is not repaired prior to a single round of DNA replication, DNA polymerases will often misincorporate adenines (via Hoogsteen base-pairing) opposite the 8-oxoG lesion. In this case, Mutyh can excise the mispaired adenine and enable Ogg1 (along with other members of the BER pathway) to correct the lesion [44].

Given the distinct roles of *Mutyh* and *Ogg1* in the BER pathway, it seems plausible that mutator alleles in both protein-coding genes could together exhibit non-additive effects on C>A mutation rates.

However, even in cells with functional copies of *Mutyh*, repair of 8-oxoG likely requires the activity of *Ogg1*. It is therefore somewhat surprising that the *D* haplotype at *Ogg1*, which further augments the effects of the *Mutyh* mutator haplotype on C>A mutation rates, has no apparent effect on its own. One possibility is that *D* haplotype overlapping *Ogg1* does, in fact, lead to elevated C>A mutation rates, but that we are underpowered to detect its effect in this study. Notably, copy-number-loss of *Ogg1* in human neuroblastoma causes a much more modest increase in C>A mutation rates than copy-number-loss of *Mutyh* [44].

Discovering mutator alleles in other systems

Numerous lines of evidence suggest that mutator alleles contribute to variation in mutation rates and spectra across the tree of life. In two natural isolates of *Saccharomyces cerevisiae*, nonsynonymous variation in *OGG1* causes a substantial increase in the C>A *de novo* mutation rate [47]. Recent analyses have suggested that mutator alleles and/or environmental mutagens have shaped mutation rate evolution both in human genomes [48] and more broadly during great ape evolution [49]. The heritability of paternal *de novo* mutation counts in the human germline has also been estimated to be between 10 and 20%, demonstrating a contribution of genetic factors to germline mutation rates [50]). However, mutator discovery remains challenging in mammalian genomes.

What conditions must be met in order to detect a germline mutator allele? Presumably, one must have access to many haplotypes, each with a reasonably large number of de novo germline mutations that remain linked to the mutator allele(s) that caused them. Recently, thousands of human pedigrees have been sequenced in an effort to precisely estimate the rate of human de novo germline mutation [6,7]. Selection on germline mutator alleles will likely prevent large-effect mutators from reaching high allele frequencies; however, if multiple mutators are active in a particular population, it becomes much more likely that a subset will be detectable by sequencing human trios [51]. Current estimates of power to detect germline mutators in human pedigrees generally assume that mutators affect all mutation types equally, and that methods for mutator discovery will rely on identifying haplotypes with excess total mutation counts [51]. However, our results in the BXD suggest that germline mutators often exert their effects on a small number of k-mer mutation types, and may be far more amenable to detection by analyzing mutation spectra instead.

Using germline mutation spectra to identify mutator alleles

Germline mutation spectra are a rich source of information about the demographic history of populations, as well as the activity of both exogenous and endogenous sources of mutation throughout time. For example, by analyzing the 3-mer mutation spectrum in a collection of human genomes, Harris and Pritchard [52] discovered a "pulse" of TCC>TTC mutation activity in European populations that likely occurred between 15,000 and 2,000 years ago, and perhaps began even earlier [53]).

Within somatic tissues, mutation spectra can also be used to uncover the mutational processes active in particular populations of cells [54]. New computational methods have been developed to extract "mutational signatures" from large databases of somatic mutations in cancer [55]. These signatures, which describe the relative frequency of each 3-mer mutation type, can often be precisely attributed to chemotherapeutic agents, exposures to environmental mutagens, or loss-of-function mutations in genes encoding DNA repair or replication proteins [54,56,57].

Although a germline mutator allele should increase the absolute count of mutations on a linked haplotype, our results demonstrate that its effects can be more easily detectable by examining mutation *spectra* instead. For example, *D* alleles at the mutator locus on chromosome 6 augment the C>A mutation rate by a factor of approximately 1.2 (Figure 3). Since C>A mutations comprise

approximately 10% of all germline mutations to begin with, *D* alleles only increase the overall germline mutation rate by about 2%. Given the depth of information that can be encoded in the mutation spectrum, we expect that mutation spectra can be further exploited to discover genetic modifiers of the mutation rate in other study systems, as well.

46. Not breathing is not an option: How to deal with oxidative DNA damage.

Enni Markkanen

DNA repair (2017-09-22) https://www.ncbi.nlm.nih.gov/pubmed/28963982

DOI: <u>10.1016/j.dnarep.2017.09.007</u> · PMID: <u>28963982</u>

47. A modified fluctuation assay reveals a natural mutator phenotype that drives mutation spectrum variation within

Pengyao Jiang, Anja R Ollodart, Vidha Sudhesh, Alan J Herr, Maitreya J Dunham, Kelley Harris *eLife* (2021-09-15) https://www.ncbi.nlm.nih.gov/pubmed/34523420
DOI: 10.7554/elife.68285 · PMID: 34523420 · PMCID: PMC8497059

48. Limited role of generation time changes in driving the evolution of mutation spectrum in humans

Ziyue Gao, Yulin Zhang, Nathan Cramer, Molly Przeworski, Priya Moorjani bioRxiv (2023-01-13) https://doi.org/grr525

DOI: https://doi.org/10.1101/2022.06.17.496622

49. Mutational Signatures of Replication Timing and Epigenetic Modification Persist through the Global Divergence of Mutation Spectra across the Great Ape Phylogeny.

Michael E Goldberg, Kelley Harris

Genome biology and evolution (2022-01-04) https://www.ncbi.nlm.nih.gov/pubmed/33983415

DOI: <u>10.1093/gbe/evab104</u> · PMID: <u>33983415</u> · PMCID: <u>PMC8743035</u>

50. Heritability of de novo germline mutation reveals a contribution from paternal but not maternal genetic factors

Seongwon Hwang, Matthew DC Neville, Genomics England Research Consortium, Felix R Day, Aylwyn Scally

bioRxiv (2022-12-17) https://doi.org/grr526

DOI: https://doi.org/10.1101/2022.12.17.520885

51. The impact of genetic modifiers on variation in germline mutation rates within and among human populations.

William R Milligan, Guy Amster, Guy Sella

Genetics (2022-07-30) https://www.ncbi.nlm.nih.gov/pubmed/35666194

DOI: 10.1093/genetics/iyac087 · PMID: 35666194 · PMCID: PMC9339295

52. Rapid evolution of the human mutation spectrum.

Kelley Harris, Jonathan K Pritchard

eLife (2017-04-25) https://www.ncbi.nlm.nih.gov/pubmed/28440220

DOI: <u>10.7554/elife.24284</u> · PMID: <u>28440220</u> · PMCID: <u>PMC5435464</u>

53. Nonparametric coalescent inference of mutation spectrum history and demography.

William S DeWitt, Kameron Decker Harris, Aaron P Ragsdale, Kelley Harris

Proceedings of the National Academy of Sciences of the United States of American

Proceedings of the National Academy of Sciences of the United States of America (2021-05-25)

https://www.ncbi.nlm.nih.gov/pubmed/34016747

DOI: <u>10.1073/pnas.2013798118</u> · PMID: <u>34016747</u> · PMCID: <u>PMC8166128</u>

54. Signatures of mutational processes in human cancer.

Ludmil B Alexandrov, Serena Nik-Zainal, David C Wedge, Samuel AJR Aparicio, Sam Behjati, Andrew V Biankin, Graham R Bignell, Niccolò Bolli, Ake Borg, Anne-Lise Børresen-Dale, ... Michael R Stratton

Nature (2013-08-14) https://www.ncbi.nlm.nih.gov/pubmed/23945592

DOI: 10.1038/nature12477 · PMID: 23945592 · PMCID: PMC3776390

55. Uncovering novel mutational signatures by

SMAshiqul Islam, Marcos Díaz-Gay, Yang Wu, Mark Barnes, Raviteja Vangara, Erik N Bergstrom, Yudou He, Mike Vella, Jingwei Wang, Jon W Teague, ... Ludmil B Alexandrov

Cell genomics (2022-11-09) https://www.ncbi.nlm.nih.gov/pubmed/36388765

DOI: <u>10.1016/j.xgen.2022.100179</u> · PMID: <u>36388765</u> · PMCID: <u>PMC9646490</u>

56. The mutational footprints of cancer therapies.

Oriol Pich, Ferran Muiños, Martijn Paul Lolkema, Neeltje Steeghs, Abel Gonzalez-Perez, Nuria Lopez-Bigas

Nature genetics (2019-11-18) https://www.ncbi.nlm.nih.gov/pubmed/31740835

DOI: 10.1038/s41588-019-0525-5 · PMID: 31740835 · PMCID: PMC6887544

57. Mutational signatures associated with tobacco smoking in human cancer.

Ludmil B Alexandrov, Young Seok Ju, Kerstin Haase, Peter Van Loo, Iñigo Martincorena, Serena Nik-Zainal, Yasushi Totoki, Akihiro Fujimoto, Hidewaki Nakagawa, Tatsuhiro Shibata, ... Michael R Stratton

Science (New York, N.Y.) (2016-11-04) https://www.ncbi.nlm.nih.gov/pubmed/27811275

DOI: <u>10.1126/science.aag0299</u> · PMID: <u>27811275</u> · PMCID: <u>PMC6141049</u>
